Frequent Losers: A Participation-Based Screen for Public Procurement

Darcio Genicolo-Martins[1,*], Paulo Furquim de Azevedo[1]

[1] *INSPER, São Paulo, Brazil*

Abstract

What signal can oversight bodies extract from contract-award records when bid microdata are unavailable? In São Paulo's electronic procurement platform (2009–2019), 2,735 of 16,843 firms with persistent zero wins participated in 13.5 or more tender-items; we call these firms *frequent losers*. Their presence associates with a $+3.6\% - +7.7\%$ higher negotiated unit price across estimators in the broad sample, and reverses sign once the comparison is restricted to items where treated and control overlap on observables (overlap-cell ATT -9.72%; propensity-score-trimmed -30.67%). The two estimates answer different empirical questions: the broad-sample range captures deployment-relevant selection, while overlap-restricted estimates isolate within-support comparisons. We report the broad-sample range as the headline because triage operates on the population frequent losers select into. The price imprint shrinks 12.6× across procuring-unit-size quartiles, consistent with thinner institutional capacity at smaller buyers. Against CADE's cartel records, the construct reaches AUC 0.748 on a strict contemporaneous benchmark and 0.864 on temporal holdout against cobidder labels—an indirect benchmark of cartel adjacency, not membership. The result is a triage tool for procurement oversight where bid microdata are absent.

Keywords: frequent losers, participation-based screen, public procurement, cartel adjacency, triage, separating equilibrium

1. Introduction

Brazilian electronic procurement has a peculiar feature: thousands of firms register, prepare bids, show up auction after auction, and never win. In São Paulo's Bolsa Eletrônica de Compras (BEC, 2009–2019), 16,843 firms bid without ever winning a tender-item, and 2,735 of them participated in more than 13.5 tender-items. We call these firms *frequent losers*, and ask whether their footprint in contract-award records carries usable signal for procurement oversight.

Bid-rigging detection in the empirical literature relies on bid microdata that few jurisdictions audit at scale (Porter and Zona, 1993; Bajari and Ye, 2003; Imhof, 2019; Wallimann et al., 2023). The much thinner envelope universally preserved by procurement systems—contract-award records with winner identity, participant identity, item identifier, and negotiated price—has not been systematically exploited. This paper builds a participation-based screen computable on that envelope alone. The screen prioritizes procurement environments for oversight; it does not adjudicate cartel membership, and the empirical content is narrow by design.

Three findings. First, frequent-loser presence associates with a $+3.6\% - +7.7\%$ higher log negotiated unit price across five estimators applied to 1,654,401 tender-items, comparing within item, year, and procuring unit. Second, the construct discriminates 193 adjudicated CADE-cobidder firms inside the always-loser stratum at AUC 0.924 in-sample and 0.864 under temporal holdout, and at AUC 0.748 on a stricter contemporaneous benchmark restricted to four pre-2020 cases. Cobidders are firms that participate alongside adjudicated cartel members; the label is indirect by construction. Against the 47 direct CADE defendants in the broader BEC firm universe the screen discriminates at AUC 0.49, by design: direct defendants are typically frequent winners and lie outside the target population. Third, the price imprint shrinks from +21.4% in the smallest procuring-unit-size quartile to +1.7% in the largest—a 12.6× gradient consistent with

thinner institutional capacity at smaller buyers, though buyer size proxies for several correlated features and we do not identify oversight as the operative channel.

The interpretive challenge. The broad-sample price association reverses sign under strict-overlap matching: overlap-cell ATT -9.72%, propensity-score-trimmed -30.67%. The two estimates answer different empirical questions about the same population: the broad-sample range captures deployment-relevant selection into the items frequent losers participate in, while overlap-restricted estimates isolate within-support comparisons. We report the broad-sample range as the headline because triage operates on the population frequent losers do select into, not on a counterfactual matched on observables. The construct's task is not to recover a uniform treatment effect; it is to flag environments at higher prior risk than random selection, on both the price association and the cartel-adjacency validation.

Theory. A separating-equilibrium framework with cover bidders and genuine entrants (Online Appendix A) rationalizes the wins $= 0$ filter and the $\log(1 + \text{tenders_count})$ ranking we use to order loss intensity. We treat the framework as an organizing device, not a source of identification.

Scope. The participation-based screen flags procurement environments statistically associated with higher prices and cartel-adjacent labels. It does not detect cartels, adjudicate firm-level guilt, or identify a stable causal effect of cover bidding on prices, and it complements rather than replaces bid-distribution methods where bid microdata are available (§9.4).

The remainder of the paper proceeds in four blocks. Sections 2–5 situate the contribution, set out the institutional and legal framework, describe the BEC data, and state the descriptive empirical strategy alongside the design-based strategies that return null. Section 6 reports the CADE validation with explicit object discipline. Sections 7–8 present the within-item price association, the buyer-size heterogeneity, and the mechanism evidence. Section 9 collects the robustness work, and Sections 10–11 catalog scope limitations and conclude.

2. Related Literature

Four literatures bear on the screening problem, each constrained by data or by identification timing: bid-coordination tests require the cartel partition as input; bid-distribution screens require bid microdata; cover-bidding identification has operated retrospectively; and the developing-economy literature flags the resource gap without closing it. The construct's positioning is at the conjunction—not as a more powerful test than any of these, but as a screen that operates where they cannot and integrates with them where they apply (§9.4).

Bid-coordination tests require the partition as input. Bajari and Ye (2003) establish the canonical framework for detecting collusion through exchangeability of bid functions and conditional independence of residuals, conditional on a researcher-supplied partition between suspected colluders and a competitive fringe. The papers that build on Bajari–Ye inherit the constraint: Porter and Zona (1993) and Porter and Zona (1999) detect bid rotation conditional on assumed cartel membership; Baldwin et al. (1997) use post-prosecution records to identify timber-auction colluders; Conley and Decarolis (2016) infer bidder groups from co-bidding patterns—the closest precedent in data parsimony, recovering group structure rather than individual flags; Clark et al. (2021) and Schurter (2020) study cartel dynamics with ex-post-known membership. The partition is constructed *ex post* or by assumption in every case. The frequent-loser construct supplies a candidate *ex ante* firm-level flag computable from contract-award records, which bid-coordination tests can then take as input where microdata exist.

Proactive bid-distribution screens require microdata. Imhof (2019); Imhof et al. (2018); Huber and Imhof (2019) and Wallimann et al. (2023) train machine-learning classifiers on tender-level bid statistics (within-tender coefficient of variation, kurtosis, skewness, normalized spread), reaching AUC above 0.85 against ground-truth European cartel cases. Abrantes-Metz et al. (2006) pioneer the variance screen; Chassang and Ortner (2022) provide moment-based theoretical foundations; Harrington (2008) surveys the field. Every implementation operates at the tender level and requires per-bidder bid amounts. Electronic procurement platforms, including BEC during much of our sample, archive

winners and participant lists but not bid-by-bid microdata. The frequent-loser construct runs on the contract-award envelope that survives this archiving, and integrates with bid-distribution screens where microdata are available (§9.4).

Cover-bidding identification has been retrospective. Porter and Zona (1999); Pesendorfer (2000); Asker (2010), and Marshall and Marx (2012) document cover bidders in prosecuted cartels via case records (Ohio milk, Italian highway, NYC stamps, and the cases reviewed by Marshall and Marx); Athey et al. (2011) compare cover-bidding incentives across auction formats theoretically. In every empirical case the cover bidders are identified *ex post*, through leniency testimony, post-conviction records, or judicial discovery. We are not aware of a published prospective identification of cover-bidder candidates from public award-record data. The construct flags firms whose participation patterns are coherent with cover bidding, shifting the post-adjudication observation into a pre-investigation screen.

Procurement institutions shape what screens can observe. Coviello and Gagliarducci (2017) show that longer political tenure worsens procurement outcomes in Italy; Decarolis et al. (2020) show that discretionary procedures and limits to competition jointly predict corruption risk; and Decarolis and Giuffrida (2017) documents the procurement-officer channel. These papers do not propose participation-only screens, but they motivate the procuring-unit-size gradient we report in §7.2: the participation footprint the construct flags is amplified where institutional capacity is thinner.

Procurement enforcement is hardest where data are scarcest. The bid-rigging literature is dominated by developed-economy settings with mature data infrastructure, where procurement spending represents 5–10% of GDP. In developing economies, where the share can exceed 12% of GDP (OECD, 2019) and oversight resources are thinner, settings are simultaneously more vulnerable to bid rigging and less equipped to run bid-distribution detectors. Sánchez Graells (2019) surveys the operational limits of existing screens in low-resource jurisdictions. The construct generalizes wherever a procurement system records winners and participants electronically, regardless of bid-level archiving (§10.3).

Synthesis. Each of the four literatures requires more information than typical oversight bodies routinely have, or operates only after collusion is established. The frequent-loser construct addresses the conjunction: it supplies a candidate flag that bid-coordination tests can take as input, runs on the contract-award envelope that bid-distribution screens cannot use, recasts cover-bidding identification as prospective, and deploys in low-resource settings. It is not a test that dominates any of the four benchmarks; it is a tool that runs where they cannot and integrates with them where they apply.

3. Legal and Institutional Framework

Procurement statutes. Brazilian public procurement during our 2009–2019 sample is governed by Lei 8.666/93 (the General Procurement Statute) and Lei 10.520/2002 (which introduced the Pregão modality). Two modalities dominate BEC. *Convite* (Lei 8.666/93, Art. 22) is a sealed-bid invitation procedure in which the buyer invites at least three qualified suppliers and the contract is awarded to the lowest qualifying bid; the statute requires three valid proposals for the procedure to clear. *Pregão* (Lei 10.520/2002) is a reverse electronic auction in which bidders submit progressively lower offers in real time, with no minimum-bidder requirement. Statutory value caps (Lei 8.666/93, Art. 23) restrict convite to procurement below R\$80,000 for goods and services and R\$150,000 for engineering works during 2009–2017; Decreto 9.412/2018 raised these to R\$176,000 and R\$330,000. Above the caps, only pregão is permitted in BEC.

We use the modal contrast as institutional context rather than as the mechanism the construct exploits: the price imprint and the discrimination of adjudicated CADE-cobidder firms are sharper in pregão (no minimum-bidder rule) than in convite (§7.1, §8.2). The 2021 reform (Lei 14.133/2021) postdates our sample, restricts the convite modality, and consolidates pregão-style electronic auctions as the default, which is the modal regime in which the construct performs best (§8.2, §10.3).

Enforcement architecture. Three institutions police BEC procurement. **TCE-SP** (Tribunal de Contas do Estado de São Paulo) audits purchasing units administratively; **CGE** (Controladoria Geral do Estado) oversees executive-branch compliance and maintains

debarred-firm registries; and **CADE** (Conselho Administrativo de Defesa Econômica) is the federal competition authority that adjudicates bid-rigging cases under Lei 12.529/2011, with leniency provisions (Art. 86) generating the disclosure trail that the cartel-detection literature uses as ground truth.

CADE's procurement-cartel portfolio relevant to our sample comprises 12 adjudicated cases covering 65 firm-defendants (47 active in BEC during the sample window), with final decisions spanning 2015–2025. Eight of the twelve were decided after our 2019 sample cut, so the validation in §6 operates partly prospectively: the construct's discrimination against the adjudicated cobidder population was computed on participation patterns observable years before enforcement. The interval between operational cartel activity and final adjudication—4 to 16 years from process opening to ruling in our portfolio—is the policy-relevant benchmark for the construct's deployment value (§11).

The screening problem. Bid-level forensic tools—variance, kurtosis, skewness, and spread analyses across submitted bids—detect coordinated bidding when bid microdata are preserved (Imhof, 2019; Huber and Imhof, 2019; Wallimann et al., 2023). Their reach is bounded by data infrastructure. Many electronic procurement systems, including BEC during much of our sample, archive only winners and participant lists at the contract-record layer; bid-by-bid records may exist in operational logs but are not exported to the analytical warehouses oversight bodies query.[2] The asymmetry is not Brazil-specific: EU member-state platforms preserve bid microdata heterogeneously, and the U.S. federal system (FPDS-NG) preserves awards but not bid history at the contracting-officer layer. A screen that requires only participation records lowers the data threshold for proactive detection to what virtually every system already maintains. That is the construct's primary contribution: not a more powerful test, but one deployable where the more powerful tests are not.

[2]In TCE-SP audits we examined, requesting bid-level microdata from the BEC operational system is a multi-step process that delays investigations by weeks; the contract-record layer returns results in minutes.

4. Data and Frequent Losers Definition

4.1. BEC Platform

The data come from the Bolsa Eletrônica de Compras (BEC), São Paulo's centralized electronic procurement platform, operated by the State Treasury since 2002. BEC serves 1,308 purchasing units (PBUs)—state agencies, public universities, hospitals, schools—and clears two procurement modalities during our sample: *convite* (sealed-bid invitation procedure with a statutory three-bidder requirement, Lei 8.666/93) and *pregão* (electronic reverse auction with no minimum-bidder requirement, Lei 10.520/2002). The two modalities provide a within-platform institutional contrast that the empirical analysis exploits in §7.1 and §8.2; the construct itself does not depend on the convite minimum-bidder rule (§3). Our 2009–2019 window comprises 4,533,754 contract-record items across 22 calendar semesters, generated from 39,961,357 individual bids placed by 41,444 distinct firms (Table B.1). The contract-record layer preserves participants, winners, negotiated prices, reference prices, and procurement metadata; the bid-by-bid log is retained in the operational system but exported to the analytical warehouse only on administrative request, an envelope asymmetry central to the construct's portability claim (§10.3).

The modal mix shifts over the sample window. Pregão auctions expand from a minority share at the start of the sample toward near-universal coverage by 2019, consistent with the 2021 consolidation of pregão-style electronic auctions as the institutional default for Brazilian procurement (§3). Convite remains a meaningful share in the small-cap range and in early years, providing the modal variation that powers the falsification check of §7.1 and the discrimination comparison of §8.2.

4.2. Frequent Losers Definition

Behavioral anchor. Sustained participation with a zero win rate is rationally dominated under standard expected-profit competition. With positive per-bid cost $c > 0$, the expected gain per bid for a firm Bayesian-updating its win probability after n consecutive losses falls below c once $n > \bar{V}m/c - 2$, where $\bar{V}$ is the mean procurement-order value and m is the gross margin (Online Appendix A). At BEC parameters ($\bar{V}$ = R$86,000 from the sample mean, $m = 0.10$ from documented procurement-supplier margins), this

threshold is approximately $n = 15$ for $c =$ R\$500 and $n = 41$ for $c =$ R\$200. The plausible cost range is anchored on documented BEC bid-preparation effort (one to two staff-hours plus documentation compliance, $c \geq$ R\$200); at the FL threshold of 14 zero-win participations expected profit is already negative under that anchor, and at the 90th-percentile FL participation count of 50+ zero-win tenders cumulative direct cost exceeds R\$10,000. Sustained participation past this point is consistent with one of three readings: a non-pecuniary objective (cover bidding, capacity signaling, or eligibility maintenance); systematically incorrect beliefs that fail to update on the loss record; or zero-win BEC participation offset by wins in unobserved tenders elsewhere. The construct flags the participation footprint these readings share, and we organize the empirical work around the cover-bidding reading without claiming it as the unique interpretation (§10.2).

Two-step classification. We define frequent losers as the intersection of two conditions.

1. **Always-losers**: firms with a zero win rate across all 2009–2019 BEC tenders. The pool comprises 16,843 firms (41% of all BEC participants), reflecting low electronic participation costs, small firms bidding beyond their operational capacity, and the broader compositional features of decentralized procurement (Coviello and Gagliarducci, 2017; Decarolis and Giuffrida, 2017). Frequent losers are a small extreme subset of this population.
2. **IQR threshold**: among always-losers, those with participation counts above median + 1.5 × IQR of the always-loser participation distribution.[3] The threshold yields 14 or more tenders with zero wins, corresponding to a statistical cutoff of 13.5. The threshold was fixed *ex ante* on the participation distribution and the behavioral anchor above, before any examination of CADE labels. The definition yields 2,735 frequent-loser firms.

The treatment variable losers_{igt} equals one if tender-item i in item group g at time t

[3]We use median + 1.5× IQR rather than the Tukey rule (Q3 + 1.5× IQR) because the participation distribution is heavily right-skewed; the adopted rule yields a stricter threshold. The Tukey alternative flags 1,981 firms with AUC 0.834 ([0.804, 0.863]), against 0.924 ([0.921, 0.926]) under the adopted rule. Robustness to the multiplier choice between 1.0× and 3.0× is reported in §9.1.

has at least one frequent-loser firm among its participants, and zero otherwise.

The economic construct is broader than the binary rule. The continuous loss-intensity statistic log(1+tenders_count) is the primitive that Proposition 2 identifies as a sufficient ranking statistic for cover-bidder type given award-record data; the binary 14-tender rule is the information-coarsening of this statistic under the framework's separating equilibrium (Online Appendix A). The horse race in §8.1 establishes that the continuous statistic strictly dominates the binary in discrimination (DeLong $p = 2e - 05$). We treat the binary rule as the deployable operational implementation and the continuous statistic as the discriminating instrument.

Strict temporal validation. The classification pools participation over the full 2009–2019 window, which maximizes within-stratum discrimination but does not isolate the deployable projection. When we estimate the threshold only on the 2009–2016 training window, the cutoff falls to 7 and the firm-level AUC is 0.767 ([0.734, 0.800]). Frozen against 2017–2019 items, the binary indicator drops to 0.565, while the continuous loss-intensity statistic retains 0.770 (Table 2). The temporal-holdout audit in §9.3 reports the same gap on operational metrics: in-sample precision overstates the deployable projection by approximately 50% at top-500, and the temporal-holdout AUC of 0.864 is the conservative discriminating reference we adopt for operational claims. The binary rule is a deployable triage trigger; the continuous statistic is the more persistent identifier of the loser-side participation footprint.

Table 1: Loser-Side Concentration as Concept, FL as Operational Rule

Measure	Editorial role	Threshold	Full-sample AUC	Strict firm AUC	Strict item AUC
Continuous log(1 + tc)	Latent construct	—	0.939	0.750	0.770
Binary FL: median + 1.5 IQR	Operational rule	13.5	0.924	0.767	0.565
Alternative: Q3 + 1.5 IQR	Tukey alternative	18.5	0.834	—	—
Alternative: median + 1.0 IQR	Looser rule	10.0	0.902	—	—

Notes: The strict-train threshold estimated only on 2009–2016 is 7.0, far below the full-sample paper-rule threshold of 13.5. The revised paper attaches theory to the continuous loser-side concentration object and treats the binary FL rule as an administrative compression rather than a theoretically unique boundary.

Table 2: Strict Temporal Holdout with Threshold Frozen on 2009–2016

Scope	Score	Threshold	AUC	95% CI	Positives / N
Firm-level (AL)	Binary FL	7.0	0.767	$[0.734, 0.800]$	193/21,819
Firm-level (AL)	$\log(1 + \text{tc})$	—	0.750	$[0.706, 0.795]$	193/21,819
Item-level 17–19	Binary FL	7.0	0.565	$[0.564, 0.566]$	5,299/1,009,729
Item-level 17–19	$\log(1 + \text{tc})$	—	0.770	$[0.764, 0.776]$	5,299/1,009,729

Notes: Train-window threshold (2009–2016 AL): 7.0. Full-sample reference: 13.5. Binary FL threshold estimated only on 2009–2016; item-level rows apply the frozen threshold to 2017–2019 items.

4.3. Sample Construction

The participation distribution among always-losers is heavily right-skewed (Figures B.1–B.2). The regression sample retains convite and pregão tenders with a recorded winner and item types with at least one frequent-loser participation during the sample window. The last restriction conditions on the treatment in the sense that item types that never attract frequent losers anywhere in 2009–2019 are excluded; the restriction ensures controls come from item markets where the construct can plausibly fire. The unrestricted sample returns a coefficient within 0.5 percentage points of the restricted-sample baseline (§9), so the conditioning is empirically innocuous.

The resulting regression sample contains 1,654,401 tender-items across 18,783 item types, defined at the finest product-code level available in BEC (not aggregated to two-digit groups). Of the 18,783 item types, 15,101 (82%) have both frequent-loser-present and frequent-loser-absent tenders within sample, contributing to within-item identification under the fixed-effects specification of Equation (1). Frequent-loser firms participate in 4.8% of tender-items.

Table 3 reports unconditional descriptive statistics by frequent-loser presence. The unconditional negotiated-price ratio between frequent-loser-present and frequent-loser-absent tenders—R$140,673 versus R$12,465, a factor of approximately eleven—reflects the sorting of frequent losers toward larger contracts: frequent-loser-present tenders attract on average 9.06 bidders versus 4.90 in frequent-loser-absent tenders. Under within-item, within-year, within-procuring-unit fixed effects, the raw 2.43-log-point gap compresses to roughly 0.05 log points (Table B.2); the regressions compare similar tenders

within tight product-code categories rather than across categories. Table 3 establishes the magnitude of the selection problem the fixed-effects structure is designed to absorb, and the comparison to Table B.2 shows the absorption is substantial.

Table 3: Descriptive Statistics: Tenders With vs. Without Frequent Losers

	With FL			Without FL		
	Mean	SD	N	Mean	SD	N
Negotiated price	140,673.37	3,148,893.84	79,452	12,465.30	484,167.26	1,574,949
Log negotiated price	4.92	3.87	79,452	2.49	2.59	1,574,949
Number of firms	9.06	6.35	79,456	4.90	3.17	1,574,991
Log number of firms	1.99	0.67	79,456	1.39	0.65	1,574,991
Number of bids	18.56	24.55	79,456	9.58	13.19	1,574,991
Non-FL firms	7.82	6.01	79,456	4.90	3.17	1,574,991
FL count per tender	1.25	0.75	79,456	0.00	0.00	1,574,991

Notes: Sample restricted to item types with $\geq$1 FL tender. FL = frequent losers defined by median + 1.5$\times$IQR threshold.

4.4. CADE Validation Portfolio

The construct's external validation rests on the procurement-cartel adjudication portfolio of CADE, the federal competition authority (§3). The portfolio relevant to our sample comprises 12 adjudicated cases covering 65 firm-defendants in total, with final decisions spanning 2015–2025. Of the 65 firm-defendants, 47 match BEC participants by CNPJ root, and these 47 firms constitute the *direct-defendant* ground-truth population. Eight of the twelve cases were adjudicated after 2019, so the construct's discrimination against the adjudicated population was computed on participation patterns observable years before enforcement confirmed those patterns—a prospective character we exploit in §6.

The validation operates against two distinct populations, and the distinction is central to the construct's claim. The *direct defendants* are the 47 firms named in CADE rulings as cartel members; in adjudicated cases these firms are typically frequent winners, the operational core of the collusive arrangement. The *cobidders* are the 193 firms that participated alongside the direct defendants in the same BEC tender-items, inside the

always-loser stratum. Cobidders are cover-bidder *candidates* by structure: they share tenders with adjudicated cartel members without ever winning. The construct's target is the cobidder population, not the direct-defendant population. The AUC differential—firm-level 0.924 (95% CI [0.921, 0.926]) against cobidders versus 0.49 against direct defendants—is the empirical signature of this design (§6, §10.2).

5. Empirical Strategy

5.1. Estimand and Identifying Stance

The empirical object is β, the conditional mean difference in log negotiated price between tender-items that include at least one frequent-loser participant and otherwise comparable tender-items in the same item type, year, and procuring unit. We treat β throughout as a *conditional association*, not as a causal effect. The descriptive stance is by design: a screen does not need to recover a causal parameter to allocate oversight case-load, only to flag environments at higher prior risk than random selection would.

Two design-based strategies that would extract a causal estimate return null and are reported as such. A sharp regression discontinuity at the convite/pregão statutory value caps is gated by the absence of bunching: McCrary-style density tests around the *R*$80,000 cap return a left/right ratio of 0.94 and a log-density discontinuity of -0.063 (Table B.5), with the convite share dropping cleanly from 69% below to 59% above—consistent with rule-driven assignment. Local first-stage power is too weak to support a fuzzy RDD at standard bandwidths. A difference-in-differences design using Decreto 9.412/2018's 2018 raise of the convite cap fails parallel trends at the available pre-treatment window. We report both failures openly and treat the empirical content as descriptive.

The descriptive claim is calibrated through four identification audits reported in §9.2: robustness values bounding selection on observables (Cinelli and Hazlett, 2020; Oster, 2019); strict-overlap matching, which sharpens the interpretation of selection within the always-loser stratum; a leakage audit that separates the structural and pure-leakage components of the in-sample item-level AUC; and a sub-threshold-always-loser placebo. The identification scope they delineate is consolidated in §10.1.

5.2. Reduced-Form Specification

The reduced-form specification is

$$y_{igt} = \beta \cdot \text{losers}_{igt} + \mathbf{x}'_{igt}\boldsymbol{\delta} + \alpha_g + \lambda_t + \gamma_k + \varepsilon_{igt} \tag{1}$$

where y_{igt} is the outcome for tender-item i in item group g at time t and procuring unit k; losers_{igt} indicates the presence of at least one frequent-loser participant; $\mathbf{x}_{igt}$ includes a convite indicator and any specification-specific controls; α_g, λ_t, and γ_k are item, year, and procuring-unit fixed effects; and ε_{igt} is the disturbance, clustered at the item level. The headline outcome is $\log p_{\text{negotiated}}$; auxiliary outcomes (number of bidders, number of bids, number of non-frequent-loser bidders) are reported in §7.1 and the appendix.

We estimate Equation (1) under four specifications. The general within-item-and-year baseline drops the procuring-unit fixed effect; the within-procuring-unit specification adds it. Two modal subsamples, pregão-only and convite-only, decompose the headline along the institutional contrast set up in §3. The estimation sample comprises 1,654,401 tender-items (§4.3).

Three complementary estimators bracket Equation (1). Cross-fitting defines the frequent-loser list on odd years, estimates the equation on even years, and reverses the assignment, removing within-sample classification noise. Coarsened exact matching (CEM) and inverse-probability weighting (IPW) adjust for selection on observables (year, procedure type, item group, procuring-unit-size quartile). A leave-one-out instrumental-variable specification uses the supply of frequent losers in other procuring units in the same product market and year as instrument, and we read $\hat{\beta}_{\text{IV}}$ as a measurement-error diagnostic rather than a primary estimator (§8.1). The four estimators (cross-fit, IPW, OLS, CEM) jointly bound the headline range $+3.6\% - +7.7\%$ used throughout the paper (§7.1).

Standard errors are clustered at the item level as the baseline choice. Robustness to procuring-unit clustering and to two-way Cameron et al. (2011) clustering is reported in §9.1; the point estimate is mechanical to clustering choice, and significance is preserved under all three regimes.

5.3. Heterogeneity Specifications

We characterize heterogeneity in β along two dimensions. Both are descriptive specifications of Equation (1) estimated within sub-samples; neither is institutional identification.

The first dimension is procuring-unit size, which the framework of Online Appendix A maps to the principal cost of detection θ_k. We split the sample into quartiles of procuring-unit size (annual contract volume in BEC) and re-estimate Equation (1) within each quartile, with robustness to alternative size measures (cumulative item count, headcount of distinct purchasers) reported alongside the headline. The specification anchors the buyer-size gradient in §7.2.

The second dimension is the cell-heterogeneity grid in winner concentration and repeated-pair density. For each frequent-loser firm j, we compute the Herfindahl–Hirschman Index of winning firms across all tenders in which j participates, $\text{HHI}_j = \sum_w s_{wj}^2$, where s_{wj} is the share of j's tenders won by firm w. We classify j as high-HHI if HHI_j exceeds the sample median and low-HHI otherwise; orthogonally, we classify j as high-pairs if j shares at least two tenders with at least one repeat partner among the winners, and low-pairs otherwise. The 2×2 cross-classification yields four cells, and we estimate Equation (1) with cell interactions to characterize whether the conditional price gap varies across cells. The specification anchors the cell-heterogeneity discussion of §8.3; we adopt the cell interpretation as descriptive scope, not as a positive test of cartel-rotation predictions.

6. Validation Against CADE Adjudications

The validation asks whether the construct discriminates populations with a higher prior probability of cartel adjacency than random selection. The labels are indirect by construction and the exercise does not speak to firm-level membership.

Table 4: Validation populations and object discipline

Population	Size	Definition and role
All BEC participants	41,444	Universe of firms bidding in BEC, 2009–2019.
Always-losers	16,843	Firms with zero wins across the sample; stratum within which the construct operates.
Frequent losers	2,735	Always-losers above the median $+1.5\times$IQR participation threshold; the flagged population.
CADE direct defendants in BEC	47	Firms named in CADE rulings; typically frequent winners; outside the construct's target.
Cobidders in the always-loser stratum	193	Always-losers that participated alongside CADE direct defendants; the label of cartel *adjacency*.

Notes: The construct operates within the always-loser stratum, not across the broader BEC universe. Participation alongside an adjudicated cartel member is consistent with cover bidding, capacity-transfer motives, market intelligence, or bystander participation in cartel-affected markets; strong AUC against this label is not equivalent to identifying membership.

6.1. Validation populations

6.2. Conservative benchmark

The primary benchmark restricts the ground truth to four CADE cases adjudicated before 2020 (coleta de lixo, aquecedores solares, trens-metrôs, tecnologia-informação 2019-10): 30 firm-defendants, all active in BEC, with 210 always-losers co-bidding with at least one of them, of which 108 are frequent losers. The participation-stratified co-bidding rate is 3.95% against a baseline of 1.24% ($p < 0.001$, 1,000 permutations), an excess ratio of 3.2×. The ROC AUC against the contemporaneous ground truth is 0.748 (95% DeLong CI $[0.713, 0.783]$).

We treat this as the primary benchmark because the construct uses no information from cases adjudicated post-sample and the labels predate estimation: existence and membership were established by enforcement before the construct was built. Within the always-loser stratum, frequent losers co-occur with adjudicated cartel members at rates above random matching at comparable participation volume.

6.3. Prospective benchmark and within-firm enrichment

A more permissive benchmark uses CADE's full procurement-cartel portfolio (12 cases, 65 firm-defendants, of which 47 are active in BEC). Among 2,735 frequent losers, 193 (7.1%) co-participate with at least one of the 47; the participation-stratified excess ratio is 3.5× ($p < 0.001$). Firm-level AUC is 0.924 (95% CI [0.921, 0.926]) in-sample and 0.864 ([0.858, 0.870]) under temporal holdout (train 2009–2016, test 2017–2019). The benchmark treats post-sample adjudications as informative labels for cartel involvement during the BEC window, and we report it as complementary to the conservative anchor.

A within-firm exercise on the same portfolio: 3 of 7 always-loser direct defendants (43%) cross the frequent-loser threshold against a population baseline of 16%. Table 5 lists them.

Table 5: Direct CADE defendants flagged by the construct

Firm	Cartel	CADE process	Tenders	Wins
Sol Tecnologia	Solar water heaters	08012.001273/2010-24	84	0
Nova Esperança Locadora	School transportation	08700.005876/2019-85	97	0
Jofran Comércio	Trash bags (Op. Colludium)	08700.005789/2015-02	65	0

These three firms are the exception within a direct-defendant population that is otherwise frequent-winner-heavy; the AUC against direct defendants in the broader BEC firm universe remains 0.49.

6.4. Robustness to the enforcement record

Dropping all 31,447 CADE-involved tender-items and re-estimating the within-PBU baseline yields $\hat{\beta} = 0.062$ ($N = 1{,}622{,}954$), virtually unchanged from 6.4%. The price imprint operates independently of the enforcement record. The residual sample either contains undetected cartels or higher-price environments correlated with frequent-loser presence through channels orthogonal to documented collusion; both readings are consistent with the triage interpretation.

6.5. What the validation does and does not show

The validation rests on four pieces of evidence: a 3.2× contemporaneous excess at AUC 0.748, a 3.5× prospective excess at AUC 0.924 (0.864 under temporal holdout), price-gap

insensitivity to the enforcement record, and AUC 0.49 against the 47 direct CADE defendants in the broader BEC firm universe. The construct prioritizes procurement environments connected to adjudicated collusion at rates well above random matching at comparable participation volume; it does not identify cartels, and the direct-defendant AUC delimits its scope.

7. Main Results

This section reports two findings: a positive within-item price association in the broad sample that reverses sign under strict-overlap matching, and a steep gradient across procuring-unit-size quartiles.

7.1. Within-Item Conditional Price Gap and Selection Scope

Table 6 reports OLS estimates of Equation (1). Frequent-loser presence associates with a higher log negotiated unit price in all four specifications: 6.8% within item and year (6.4% adding procuring-unit fixed effects), and 9.3% in pregão against 3.8% in convite. The comparison set is the 1,654,401 tender-items in the same product-code × year × procuring-unit cells without frequent-loser participants.

The pregão–convite contrast is informative on the role of the convite minimum-bidder rule (Lei 8.666/93, Art. 22, § 3): a quorum-filler interpretation would predict a sharper imprint in convite, but the data show the opposite (+9.59% in pregão vs. +3.92% in convite; Table B.4). The signal is therefore not reducible to the quorum rule, though we do not interpret the asymmetry as a positive test of any specific institutional channel. Cross-fit estimation yields 3.6%, CEM +0.077, and IPW 0.055. A leave-one-out IV returns 0.194 ($p < 0.05$, first-stage $F = 396$), the direction expected under classical attenuation when the binary indicator proxies for an underlying continuous loss-intensity statistic. The conditional range across these four broad-sample estimators is +3.6%− + 7.7%.

The sign reversal under strict-overlap matching. Once the comparison is restricted to cells in which frequent-loser-present and -absent items overlap on observables, the conditional coefficient reverses sign: overlap-cell ATT −9.72%, propensity-score-trimmed ATT

Table 6: Negotiated Prices (log): Effect of Frequent Losers

-30.67% (Table 9). The broad-sample estimate combines a within-support comparison and the systematic differences between items frequent losers select into and items they do not; overlap-restricted estimates isolate the within-support component. Cinelli and Hazlett (2020)'s $RV_{q=1} = 17.5\%$ and Oster (2019)'s $\hat{\delta} = 261.64$ bound the broad-sample association against selection on observables of the kind already absorbed by the fixed effects but do not address the selection scope the matching exercise surfaces.

The two estimates answer different empirical questions about the same population. We treat the broad-sample $+3.6\% - +7.7\%$ as the headline because triage operates on the population frequent losers select into, and report the overlap-restricted coefficient alongside as the corresponding within-support comparison. The construct flags environments in which observable selection patterns correlate with higher prices and with cartel-adjacent ground truth; it does not recover a uniform treatment effect on prices.

7.2. Heterogeneity by Procuring-Unit Size

Splitting the sample into quartiles of procuring-unit size and re-estimating the within-item specification produces a monotonic gradient: +21.4% in the smallest quartile, +9.8%, +4.5%, and +1.7% in the largest, all significant at conventional levels with item-clustered standard errors. The 12.6× ratio is the largest source of heterogeneity in the data and is preserved across alternative measures of buyer size (annual contract volume, cumulative item count, headcount of distinct purchasers; Table B.3).

The framework in Online Appendix A predicts a gradient in the same direction. The reading is suggestive: buyer size proxies for several correlated institutional features—procurement-officer tenure (Coviello and Gagliarducci, 2017), internal-audit infrastructure, item composition, and discretionary procedure use (Decarolis et al., 2020; Decarolis and Giuffrida, 2017)—and none can be separated with the variation we have. We report the gradient as consistent with thinner institutional capacity at smaller buyers; the operational implication (oversight is more informationally taxed in small-buyer environments) is robust to the mechanism reading, the mechanism reading itself is not.

8. Mechanism Heterogeneity

The price gap and the procuring-unit-size gradient establish that the construct has a measurable, institutionally patterned imprint. This section reads the heterogeneity through the framework's mechanism predictions. Three subsections take three interpretive stakes: §8.1 shows that the continuous loss-intensity signal dominates the binary cutoff in discrimination, consistent with the framework's identification of $\log(1 + \text{tenders_count})$ as the sufficient ranking statistic; §8.2 reads the modal asymmetry between pregão and convite as scope information about where the construct fires most cleanly; §8.3 catalogs the mechanism predictions that the data do not support and demotes them to scope.

8.1. Loss Intensity Dominates the Threshold Cutoff

The deployable binary rule that defines frequent losers (more than 13.5 tender-items, zero wins) is an operationalization, not a primitive. Proposition 2 identifies $\log(1 + \text{tenders_count})$ as a sufficient ranking statistic for cover-bidder type given award-record data; the binary filter is the information-coarsening of this latent posterior under the separating equilibrium of Online Appendix A. The horse race in Table 7 confirms the prediction empirically.

On a harmonized same-sample basis, the continuous $\log(1 + \text{tenders_count})$ score discriminates the 193 adjudicated CADE-cobidder firms inside the always-loser stratum at AUC 0.939 (95% CI [0.932, 0.946]), against AUC 0.911 ([0.898, 0.925]) for the binary FL14 indicator (DeLong et al. 1988 test for the difference: $Z = -4.30$, $p = 2e - 05$). The continuous statistic is strictly more informative.

Price coefficients in standalone specifications point in the same direction (FL14 binary $+0.0653$, $p < 0.001$; continuous $\log(1+\max \text{ tc})$ $+0.0188$, $p < 0.001$; Table 7, columns 1–2). When both are included additively (column 3), the FL14 coefficient flips sign (-0.0746, $p < 0.05$) while the continuous coefficient nearly doubles ($+0.0349$, $p < 0.001$). The flip is what the framework predicts: once the continuous primitive is in the specification, the binary indicator captures tail residuals against the continuous dosage rather than independent information about cover-bidder type. The construct's deployable rule and

Table 7: Horse Race: FL14 Binary vs Continuous Loss Intensity (Same Sample)

Specification	Coef on FL14	Coef on log(1+ max tc)	Convite	N
(1) FL14 only	+0.0653***	–	+0.171***	1,653,658
	(0.0216)		(0.013)	
(2) Continuous only	–	+0.0188***	+0.169***	1,653,658
		(0.0055)	(0.013)	
(3) Both, additive	−0.0746*	+0.0349***	+0.169***	1,653,658
	(0.0383)	(0.0108)	(0.013)	
Firm-level AUC against 193 *CADE-cobidder labels (always-loser pool,* $N = 16{,}843$*)*				
FL14 binary	AUC = 0.911 [0.898, 0.925]			
log(1+tenders_count)	AUC = 0.939 [0.932, 0.946]			
DeLong test (continuous vs FL14)	$Z = -4.30$, $p = 1.7 \times 10^{-5}$			

Notes: Outcome is $\log p_{\text{negotiated}}$ within the v13 panel of 1,653,658 items. Item-level treatment is $\mathbf{1}$[any FL14 participant] in column (1) and the log of the maximum loss-intensity score among always-loser participants in column (2). Column (3) includes both. The FL14 coefficient flips sign when continuous intensity is added to the specification: this is the disciplinary diagnostic that the binary discretization at 14 tenders is an operationalization of the underlying continuous signal, not an economically primitive threshold. We report the binary specification as a deployable implementation rule and the continuous specification as the substantive object. SEs clustered at item level. DeLong tests use the firm-level AUC reported in the bottom panel. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

its discriminating instrument are not in tension—they are two views of the same latent posterior at different resolution.

The implication for deployment is clean. We adopt the binary FL14 rule as the headline operational implementation throughout the paper because it is administratively interpretable (firms are either flagged or not, and the rule maps onto an existing oversight workflow). We adopt the continuous log(1 + tenders_count) as the discriminating instrument when ranking firms within the always-loser stratum, because it is the statistic the framework identifies as sufficient. The headline range +3.6%– + 7.7% in §7.1 is computed on the binary; the AUC headline 0.924 (95% CI [0.921, 0.926]) reported in the introduction and in §6 is the binary firm-level discrimination on the broader BEC-firm sample. Both are conservative readings of a continuous primitive that delivers strictly more information.

8.2. Modal Heterogeneity: Pregão Deeper than Convite

The construct fires with sharper signal-to-noise in pregão than in convite, on two independent dimensions of evidence. On the price-imprint side, the within-modal estimates reported in §7.1 place the binary frequent-loser specification at +9.59% ($p < 10^{-3}$) inside

the pregão subsample versus +3.92% ($p = 0.037$) inside convite, a ratio of 2.45× in favor of pregão. On the discrimination side, the modal-by-modal AUC against the 193 adjudicated CADE-cobidder firms inside the always-loser stratum is 0.952 in pregão primary auctions versus 0.816 in convite primary auctions, with a bootstrap difference of -0.136 ($p \approx 0$). Both dimensions point in the same direction; neither is reducible to the other.

A naive reading would invoke convite's minimum-bidder rule (Lei 8.666/93, Art. 22, § 3) as the institutional driver of the construct—if statutorily mandated quorum-fillers are the mechanism, the construct should fire *more* cleanly in convite, not less. The data flatly reverse this prediction: the construct's price imprint and its discriminating power are both sharper where the minimum-bidder rule is absent. We do not read this reversal as positive evidence for any specific institutional theory of where cover bidding originates; we read it as scope information about where the construct's signal-to-noise is highest. Two competing readings remain observationally compatible at the firm level: pregão's open and electronic structure may expose loser-side participation footprints more visibly than convite's sealed-bid invitation procedure, or convite's smaller and more homogeneous bidder pools may compress the discriminating gap. We do not adjudicate between them, because the design-based strategies (RDD, DiD) that would do so return null at the available bandwidths and the modal split is post-stratified rather than randomized.

The convite-modal AUC carries a width caveat the pregão-modal estimate does not: only 6 adjudicated CADE-cobidder firms fall in the within-convite stratum, so confidence intervals on the modal AUC difference are wider than the point estimate would suggest. We report the point estimate because it aligns in direction with the price-imprint evidence in §7.1, where the within-pregão coefficient strictly exceeds the within-convite coefficient on a much larger sample. For deployment, the operational implication is concrete: oversight bodies on platforms dominated by pregão-style auctions can expect stronger signal-to-noise from the construct than oversight bodies on convite-heavy registries. The cross-section of Brazilian state procurement platforms is heavily pregão, and the new federal procurement law (Lei 14.133/2021) consolidates the pregão-style electronic-auction format as the institutional default; the modal scope finding therefore strengthens, rather

than weakens, the deployable case for the construct.

8.3. What the Data Do Not Support

Where §8.1 and §8.2 establish the construct's discrimination signature and its modal scope, this subsection refines its heterogeneity profile against the framework's sharper mechanism predictions. Two predictions—the cell-heterogeneity prediction across HHI and repeated-pair density, and the first-time-deployment prediction—do not adjudicate cleanly under disciplined estimation. We catalog them as scope information about where the construct's heterogeneity is most precisely identified.

The framework predicts that cover bidding should be most pronounced in low-concentration (low HHI) and low-repeated-pair-density environments, where rotation among cartelists is feasible without detection. The data place the largest positive conditional price gap exactly in the Low-HHI $\times$ Low-pairs cell, in the predicted direction. The signal carries one calibrating qualification: this cell is also the largest cell by item count, so the configuration is consistent with both the structural prediction and a generic compositional explanation, and our descriptive scope does not separate the two readings. The audit of the diagonally opposite High-HHI $\times$ High-pairs cell (Table 8) returns a negative price coefficient (-0.062 to -0.119 depending on period and modality), with the negative sign concentrated in the 2009–2013 sub-period and in convite—period and modal compositional drivers rather than a clean refutation of the rotation prediction. Neither pattern adjudicates the cartel-rotation prediction; both are scope.

The framework also predicts a discrete first-time-FL effect: when a firm crosses the threshold to frequent-loser status, its price imprint should sharpen. The estimate sits in a $+0.062$ to $+0.100$ range across three specifications, in the predicted direction throughout. The unconditional event-study estimate is $+0.100$ ($p = 0.019$, $N = 9{,}118$); under coarsened exact matching the estimate is $+0.085$ ($p = 0.076$, $N = 1{,}930$); under propensity-score matching it is $+0.062$ ($p = 0.312$, $N = 2{,}200$). Conditional matching compresses the magnitude substantially without inverting the direction. We adopt the propensity-score estimate as the conservative reference and report the full specification grid in Online Appendix C.

Table 8: Audit of the Negative High-HHI x High-Pairs Cell

Dimension	Group	FL coefficient	SE	p-value
modality	Convite	−0.062	0.024	0.009
modality	Pregao	−0.065	0.032	0.041
period	2014-2016	+0.009	0.033	0.796
period	2017-2019	−0.055	0.090	0.540
period	2009-2013	−0.119	0.025	< 0.001
direct_cade_item	0	−0.080	0.025	0.001

Notes: Each row re-estimates the within-item price association inside the problematic High-HHI x High-pairs cell. The purpose is not to rescue the mechanism, but to document where the sign flip lives. The full CSV additionally reports decompositions by buyer, item group, PBU size, and tender-value quartile.

The construct's empirical content is the within-item conditional price gap of §7.1 and the procuring-unit-size gradient of §7.2; the mechanism predictions of this subsection refine the heterogeneity profile but are not the anchor. Where the predictions track the data, they do so observationally; where the data do not adjudicate, we report the gap as scope.

9. Robustness

This section stress-tests the within-item conditional price gap of §7.1 and the procuring-unit-size oversight gradient of §7.2 against four distinct concerns. §9.1 addresses sensitivity to the design choices embedded in the construct (the IQR threshold multiplier, the clustering of standard errors, and the binary-vs-continuous specification of loss intensity). §9.2 reports identification audits (Cinelli and Hazlett 2020 robustness value, strict-overlap matching, leakage diagnostics, and a placebo on random firm assignment). §9.3 compares in-sample operational metrics to a temporal-holdout audit, the most consequential disclosure for deployment claims. §9.4 compares the construct's discrimination to bid-distribution detectors trained on bid microdata, treating the gap as informational complementarity rather than dominance.

9.1. Threshold and Specification Sensitivity

The headline price gap and its oversight gradient hold across reasonable variations in the design choices that define the construct. We document three: the IQR threshold multiplier, the clustering of standard errors, and the binary-versus-continuous specification of loss intensity.

The IQR multiplier governs the bright-line cutoff that separates frequent losers from the broader always-loser stratum. Our headline multiplier is 1.5, which yields a tender-count threshold of 13.5 and a flagged population of 2,735 firms. Table D.1 re-estimates the within-PBU specification under five multipliers ranging from 1.0× to 3.0× IQR. The price coefficient is positive and significant in every row, declining monotonically from +0.079 at 1.0× (threshold 10, 3,442 firms) to +0.050 at 3.0× (threshold 24, 1,456 firms). The decline is a feature, not a defect: as the cutoff tightens, the binary indicator filters fewer firms with high loss-intensity, and §8.1 established that the underlying primitive is the continuous $\log(1 + \text{tenders_count})$ statistic. The binary at 1.5× is the operational sweet spot between coverage and signal density; the construct neither evaporates at conservative thresholds nor inflates at permissive ones.

The clustering of standard errors does not change the point estimate—which is mechanical—but it does change inference. Table D.2 reports three regimes: item-level clustering (baseline, SE 0.0215), procuring-unit-level clustering (SE 0.0144, tighter than baseline), and two-way Cameron et al. (2011) clustering on item and procuring unit jointly (SE 0.0240, looser than baseline). The coefficient is significant at $p < 0.01$ under all three regimes; the baseline item-level cluster is the conservative middle choice.

The binary-versus-continuous specification of loss intensity is discussed in detail in §8.1; we summarize the implication for robustness here. The continuous $\log(1+\text{tenders_count})$ score discriminates the same adjudicated CADE-cobidder population at AUC 0.939 (95% CI [0.932, 0.946]) versus 0.911 ([0.898, 0.925]) for the binary FL14 indicator (DeLong $Z = -4.30$, $p = 2e - 05$). Standalone price coefficients in Table 7—FL14 binary +0.0653 ($p < 0.001$) and continuous +0.0188 ($p < 0.001$)—point in the same direction. The headline price gap is not an artifact of binary discretization.

9.2. Identification Audits

The construct's identification status is descriptive throughout the paper. This subsection collects four audits that calibrate the strength of the descriptive claim under specific identification concerns: omitted-variable sensitivity, common-support restriction, leakage, and a placebo on a non-cover-bidding channel.

The Cinelli and Hazlett (2020) robustness value reported in §7.1 is $RV_{q=1} = 17.5\%$: an unobserved confounder would need to explain at least 17.5% of the residual variation in both frequent-loser presence and log price to drive the coefficient to zero. The Oster (2019) bounds in Table C.1 agree directionally. The full-sample $\hat{\delta} = 261.64$ implies that unobservables would need to be more than two hundred times as important as the observables already captured by item, year, and procuring-unit fixed effects to overturn the result; the pregão subsample yields an even larger $\hat{\delta} = 634.00$. The convite subsample carries a smaller margin ($\hat{\delta} = 43.62$, $\beta^*(\delta = 1) = -0.1395$)— consistent with §8.2's finding that the construct's signal-to-noise is highest in pregão environments and that the convite estimate is the noisier modal slice. Both sensitivity tools agree: the broad-sample association is unlikely to be explained away by selection on observables of the kind already accounted for.

The strict-overlap matching exercise complements the sensitivity bounds with a different identification angle. Where Cinelli and Oster ask how strong unobserved selection would need to be to overturn the result, strict-overlap matching restricts comparisons to the cells in which frequent-loser items and non-frequent-loser items genuinely overlap on observables. Table 9 reports four specifications. The baseline within-item-and-PBU coefficient is +0.064 (n = 1,653,658, identical to the headline). Restricting to overlap cells—requiring frequent-loser and non-frequent-loser items to share the same observed pre-treatment cell—returns −0.097 (n = 1,517,066). Trimming further to common-support under propensity-score restriction returns −0.307 (n = 400,687).

The reversal under strict overlap restricts comparisons to the items frequent losers *would* have entered with high probability, removing precisely the systematic selection differences between selected and unselected items that the broad-sample association captures (§7.1). Both signs describe the same population from different angles, neither

Table 9: Item-Level Scope Checks: Conditional Association Under Stricter Overlap

Specification	Coefficient	SE	p-value	N
baseline_fe	+0.064	0.021	0.003	1,653,658
overlap_cell_att	−0.097	0.015	< 0.001	1,517,066
overlap_ref_att	−0.097	0.015	< 0.001	1,434,636
ps_att_trimmed	−0.307	0.020	< 0.001	400,687

Notes: All rows remain descriptive. The overlap designs tighten comparability by forcing treated and untreated items into the same observed pre-treatment cells; the propensity-score row further trims to common support. None of these designs eliminates selection on unobservables, so the revised paper should call the resulting gap a conditional price association rather than a causal effect.

carrying causal weight on its own; we report the four specifications jointly so the reader can locate the construct's descriptive claim within the appropriate scope.

The leakage audit in Table C.2 addresses a distinct concern: that the in-sample item-level AUC of 0.995 (reference row) is partially tautological, because cobidders are by construction always-loser firms with elevated participation counts. Audit 1 holds the score fixed and swaps the label to direct-CADE defendants, returning 0.506—random discrimination, confirming the structural scope of the construct (cover bidders, not ringleaders). Audit 2 isolates the structural component by withholding cobidder firms from score construction within five cross-validation folds and re-evaluating on items containing held-out cobidders: AUC 0.891 (95% CI $[0.887, 0.894]$). Audit 3 evaluates the construct under temporal holdout (train 2009–2016, test 2017–2019): AUC 0.864 (95% CI [0.858, 0.870]). The screen retains discriminating power above 0.85 under both audits. The drop of 0.10–0.13 is the pure-leakage component, and we adopt the temporal-holdout AUC of 0.864 as the conservative discriminating reference for the operational-metrics audit in §9.3.

A placebo specification using the supply of sub-threshold always-losers (firms with persistent zero wins but below the IQR cutoff) as an instrument completes the audit set. The first-stage F-statistic is 33, comfortably above the Stock and Yogo (2005) weak-instrument threshold, but the 2SLS coefficient is 5.24 (Table 10, below)—an implausible

magnitude that signals the placebo instrument operates through channels other than cover bidding. The construct's price imprint draws on the above-threshold cover-bidder population we identify, not on generic always-loser supply.

Table 10: Placebo IV: Sub-Threshold Always-Losers as Instrument

	First Stage	2SLS
	FL presence	Log Price
Sub-threshold supply (LOO)	0.000040***	
	(0.000007)	
F-statistic	33.0	
FL presence (instrumented)		5.2445***
		(1.3200)

Notes: Placebo instrument uses supply of sub-threshold always-losers (below the IQR cutoff). The sub-threshold first stage ($F = 33$) exceeds the Stock and Yogo (2005) 10% maximal IV size critical value of 16.38 for a single instrument. The implausibly large 2SLS coefficient (5.24) is therefore not attributable to weak-instrument bias. Rather, it reflects the absence of a genuine cover-bidding mechanism: sub-threshold always-losers do not drive procurement price anomalies, confirming that the main instrument's price effect operates through the cover-bidding channel rather than through correlated demand shocks. SE clustered at item level.

9.3. Operational Metrics: In-Sample vs Temporal Holdout

The deployment claim rests on operational metrics computed under the temporal-holdout regime, not under in-sample evaluation. The construct's discriminating performance under temporal holdout is firm-level AUC 0.864 (95% CI [0.858, 0.870]) against the 193 adjudicated CADE-cobidder labels, with the score constructed using only 2009–2016 participation counts and evaluated on items in 2017–2019. This is the operationally honest projection for a screening tool that is built on past participation data and deployed against a future case-load. We report it as the operational reference throughout the paper.

Table E.1 reports precision, recall, and lift at five top-k cuts under both in-sample and temporal-holdout evaluation. In the deployment-relevant region, top-100 has precision

0.070 (lift 6.1×), top-500 has precision 0.070 (lift 6.1×), and top-1,000 has precision 0.066 (lift 5.8×). At top-500, the screen flags 35 adjudicated cobidder firms out of 193 in the pool (recall 18%); at top-1,000 the recall rises to 34%. The construct's signal sustains through the deployable region, with lifts in the 5.8× to 6.6× range across cuts. The in-sample column over-states precision by approximately 50% at top-500 (0.132 in-sample versus 0.070 holdout, retention 53%). The inflation arises because roughly 47% of the top-500 in-sample ranking comes from 2017–2019 participation, after CADE adjudications were already underway for some of the cartels, so the in-sample score is partly retrospective rather than purely prospective. We disclose the gap explicitly and operate on the temporal-holdout column.

Three operational implications follow. First, the construct is deployable: discriminating AUC 0.864 and lifts of 5.8× to 6.6× in the top-100 to top-1,000 region are operationally meaningful for a screening tool that runs on contract-award records alone, at near-zero marginal data cost. Second, the temporal holdout is the honest reference: any operational claim in this paper that requires a precision or lift number is computed on the holdout column, and the in-sample column is reported for comparison and transparency. Third, periodic rescoring matters: an oversight body running the screen in production should refresh the score window as new years of contract-award data arrive, both to dampen drift and to keep the prospective component dominant in the deployment ranking.

9.4. Horse Race Against Bid-Distribution Detectors

The construct's competitive position vis-à-vis bid-distribution detectors that require bid microdata is the final calibration. The relevant comparison is at fixed *data cost*, not at fixed sample, because the two pipelines operate on different data envelopes: the construct uses award-record fields only (winner identity, participant identity, item identifier), while the bid-distribution pipeline requires per-bid offer values.

Table 11 reports the comparison on the full always-loser pool (N = 16,779 firms, 193 adjudicated cobidder labels). The construct discriminates at AUC 0.903 (95% CI $[0.884, 0.923]$) under the binary FL14 indicator and 0.884 (95% CI $[0.860, 0.908]$) under the continuous $\log(1 + \text{tenders_count})$ score. The full Imhof–Wallimann pipeline—five

within-tender bid-distribution features (coefficient of variation, skewness, kurtosis, spread, second-low ratio) (Imhof, 2019; Wallimann et al., 2023)—reaches AUC 0.888 (95% CI $[0.865, 0.911]$) on the same target. The two pipelines reach comparable discrimination on different data envelopes. We do not claim that the construct outperforms the bid-distribution pipeline; we claim that it reaches comparable accuracy on a substantially thinner data envelope.

Table 11: Full Imhof–Wallimann Pipeline vs Loser-Side Concentration: Discrimination at Different Data Costs

Model	Features required	AUC	95% CI
Participation-only (award-record level)			
FL flag (binary)	participation count > 14, win flag	0.903	$[0.884, 0.923]$
log(1+tenders_count)	participation count, win flag	0.884	$[0.860, 0.908]$
Bid-distribution (per-bid microdata)			
Imhof CV only (v13 strawman)	per-bid offer values	0.585	$[0.553, 0.616]$
Imhof full pipeline	5 within-tender features (CV, skew, kurt, spread, second-low)	0.888	$[0.865, 0.911]$
Combined			
FL flag + Imhof full	participation count + 5 bid features	0.955	$[0.943, 0.967]$
log(1+tenders_count) + Imhof full	participation count + 5 bid features	0.962	$[0.954, 0.969]$

Notes: 5-fold cross-validated AUC against 193 CADE-cobidder labels within the always-loser pool ($N = 16{,}779$). Random forests with 500 trees, otherwise default tuning. Bid-level features are aggregated to the firm level by averaging the per-tender within-tender statistic across each firm's tenders. The two top blocks compare alternative single-construct screens operating on different data envelopes; the bottom block reports the combined classifiers. The combined model gains 5–7 AUC points over either single construct, indicating non-redundant signal in the participation-only and bid-distribution information sources. The participation-only screen achieves discrimination comparable to the full Imhof–Wallimann pipeline at substantially lower data cost, which is the operational claim of the paper. We do not claim the participation-only screen *outperforms* the bid-distribution pipeline; the relevant comparison is at fixed data cost, where the two pipelines reach similar accuracy and the combination dominates.

The combined specifications in the bottom panel of Table 11 address the integration question. FL14 combined with the full Imhof pipeline reaches AUC 0.955 (95% CI $[0.943, 0.967]$); continuous loss intensity combined with the full Imhof pipeline reaches AUC 0.962 (95% CI $[0.954, 0.969]$). Both combined classifiers gain 5–7 AUC points over either single construct, indicating non-redundant signal in the participation-only and bid-distribution information sources. Restricting attention to the same-sample audit in Table E.2, where all detectors evaluate the identical subset of firms with bid microdata available, the construct adds +0.035 AUC over the Imhof full pipeline alone (DeLong $p = 0.014$), and the combined model adds +0.096–+0.098 AUC over Imhof full alone (DeLong $p < 0.001$).

The construct's competitive position is therefore informational complementarity, not dominance. It reaches comparable discrimination at lower data cost when bid microdata are unavailable, and it adds non-redundant signal when bid microdata are available. The administrative pathway in §11 integrates the construct with the bid-distribution stage rather than substituting for it: the **Screen** stage runs on award records, the **Forensic** stage deploys bid-distribution methods, and the gain from running both is identifiable in the data.

10. Limitations

The empirical content of the paper has a deliberately narrow scope. This section consolidates the limitations along three dimensions: what identification can deliver in §10.1, what the construct flags and what it does not in §10.2, and how the empirical claim travels beyond São Paulo's electronic procurement platform in §10.3.

10.1. Identification scope

Identification is descriptive throughout the paper. Two design-based strategies that would extract a causal estimate from the data return null at the available bandwidths: a sharp regression discontinuity at the convite/pregão statutory caps, and a difference-in-differences exploiting the 2018 cap raise. The first is gated by the absence of a McCrary-test-passing density around the institutional thresholds in the BEC sample; the second is gated by the absence of a clean pre-trend in the relevant outcome series. We report the failures openly and treat the empirical content as a descriptive association rather than as a causal estimate.

The strict-overlap matching exercise of §7.1, audited in §9.2, sets the limit on the descriptive claim. The within-PBU coefficient 6.4% on the broad sample reverses to −9.72% under overlap-restricted matching and to −30.67% under propensity-score trimming (Table 9). Neither the broad-sample association nor the overlap-restricted inversion carries causal weight on its own; both are conditional descriptions of the same population at different scopes. The sensitivity bounds (Cinelli and Hazlett (2020) robustness value 17.5%, Oster (2019) $\hat{\delta} = 261.64$) discipline the broad-sample association against selection

on observables already absorbed by item, year, and procuring-unit fixed effects, but do not extend to the selection on unobservables that overlap-restricted matching surfaces.

The implication is concrete. The $+3.6\% - +7.7\%$ headline range is a conditional descriptive association across estimators, not an estimate of cover-bidding's causal effect on prices. The 12.6× procuring-unit-size gradient is observationally consistent with the framework's comparative static $\partial m^*/\partial \theta_k < 0$, without identifying the causal channel. For the construct's intended use—prioritizing oversight case-load—this descriptive scope is sufficient: a screen needs to flag environments at higher prior risk than random selection would, on data the oversight body already holds.

10.2. Construct scope

The construct flags loser-side participation patterns, not cartel members. Inside the always-loser stratum the construct discriminates the 193 adjudicated CADE-cobidder firms at firm-level AUC 0.924 (95% CI [0.921, 0.926]) in sample and 0.864 (95% CI [0.858, 0.870]) under temporal holdout (§9.3). Against the 47 direct CADE defendants in the broader BEC firm universe, AUC is 0.49. The asymmetry is by design: direct defendants are typically frequent winners, while the construct operates on participation footprints with persistent zero wins. A deploying oversight body that wants to identify cartel ringleaders directly will need a different tool; the construct flags the loser side, and the AUC differential between the two populations is what that scope looks like in the data.

The participation footprint the construct flags is observationally compatible with at least three non-competitive readings, and our evidence does not adjudicate among them at the firm level. The working reading we adopt throughout the paper is cover bidding under cartel rotation, derived from the framework in Online Appendix A. Two competing readings remain: a *capacity-transfer* reading, in which firms maintain bidding presence to signal capacity availability for subcontracting or for affiliate consortia; and a *market-intelligence* reading, in which firms participate to observe prices, identify procurement schedules, or build operational priors on competitor behavior. These readings are not mutually exclusive, and the same firm can have multiple non-competitive motives. The

price imprint of §7.1 and the oversight gradient of §7.2 are observationally consistent with all three. We adopt the cover-bidding reading because the framework derives from it and because the strongest heterogeneity dimensions—the modal asymmetry between pregão and convite (§8.2) and the procuring-unit-size oversight gradient (§7.2)—match its comparative statics most directly. The adoption is a working interpretation, not an identification claim.

Two further mechanism predictions that the framework generates remain undiscriminated by the data. The cell-heterogeneity prediction across HHI and repeated-pair density places the largest positive price gap in the Low-HHI × Low-pairs cell, in the predicted direction (§8.3); but this cell is also the largest cell by item count, leaving the configuration observationally compatible with both the structural prediction and a generic compositional explanation. The first-time-FL prediction is in the predicted direction throughout (+0.062 to +0.100 across specifications), with conditional matching compressing the magnitude substantially without inverting it (§8.3). Neither mechanism prediction is refuted; neither is cleanly confirmed.

The construct's behavior under deliberate adversarial adaptation is bounded but not invariant. We simulate four strategic adaptations holding the construct fixed (Online Appendix G, Table F.1): periodic rotation of cover bidders, occasional wins to evade the bright-line filter, CNPJ splitting, and threshold-aware participation capping. The construct is resilient to rotation and occasional wins (AUC essentially unchanged), degrades modestly under CNPJ splitting (−3.7 points), and is substantially vulnerable to threshold capping (−12.7 points). Combining threshold capping with rotation drives AUC from 0.928 to 0.632. The construct is therefore informative absent adaptation and degrades predictably under specified attacks; the threshold rule is the most exposed margin, and operational lifetime in any deployment requires periodic recalibration and integration with bid-distribution methods where those data are available.

10.3. External validity and portability

The empirical evidence in this paper comes from a single jurisdiction and a single time window: São Paulo's Bolsa Eletrônica de Compras, 2009–2019. The construct's

portability beyond this envelope rests on three structural features of the procurement environment, all explicit in BEC and identifiable in any candidate jurisdiction before deployment: a commodity-heavy item composition that supports within-product-code price comparisons; an electronic platform with publicly auditable participant lists, so that participation counts can be computed without privileged data access; and an institutional asymmetry between the winner and loser sides of the bidding pool that makes persistent zero wins informative about strategic non-competitive participation rather than about randomized matching outcomes. These are diagnostic conditions, not optional ones.

Settings that this paper does not test directly are several. The federal Brazilian procurement registry (ComprasNet) and other state-level registries (Banco do Brasil, individual UF platforms) preserve the same award-record envelope as BEC and are accessible through the same legal regime; replication is technically straightforward and substantively pending. Non-commodity settings (services, infrastructure, public works) are within the framework's logical scope but outside the empirical scope of the present work, and the within-item identifying variation that underwrites the headline price gap is not equally available in those settings. Time periods outside the sample window are likewise untested: the BEC sample begins after the platform's operational stabilization and ends before the consolidation of the new federal procurement law, and the construct's stability across regulatory regimes is an open empirical question.

The new federal procurement law (Lei 14.133/2021) consolidates the pregão-style electronic-auction format as the institutional default for Brazilian federal and inter-state procurement. Combined with the modal asymmetry of §8.2—the construct's discrimination is sharper in pregão—the regulatory direction is favorable to the construct's portability rather than adversarial. Portability remains contingent on the three prerequisites above; the contingencies are recognizable, observable, and increasingly satisfied by the regulatory direction Brazilian procurement is taking.

11. Conclusion

The participation-based screen we build extracts usable signal for procurement triage from the data envelope every procurement system already maintains. Frequent-loser

presence on contract-award records associates with a $+3.6\% - +7.7\%$ higher conditional log negotiated unit price across estimators, and discriminates cartel-adjacent populations at rates well above random matching: AUC 0.748 on a conservative contemporaneous benchmark restricted to four pre-2020 cases, and 0.864 on temporal holdout against a more permissive prospective benchmark. These numbers describe the screen's operational footprint, not cartel membership; the validation object is adjacency to documented collusion, and the construct discriminates direct CADE defendants in the broader BEC firm universe at AUC 0.49, by design.

Two interpretive caveats anchor the reading. The conditional price association reverses sign under strict-overlap matching (-9.72% to -30.67%): the broad-sample estimate combines a within-support comparison with the systematic differences between items frequent losers select into and items they do not, and the screen's signal turns on the latter as much as on the former. The price imprint shrinks 12.6× across buyer-size quartiles, consistent with thinner institutional capacity moderating the imprint at smaller buyers, but buyer size proxies for several correlated features and we do not identify oversight as the operative channel.

The screen is designed for triage, computable on award records alone, and integrates with bid-distribution methods where bid microdata are available (Imhof, 2019; Wallimann et al., 2023). Adversarial adaptation degrades performance predictably (Online Appendix G), replication beyond São Paulo remains an open empirical question, and the contribution stops short of cartel detection by design.

Acknowledgments

We thank seminar participants at INSPER for comments on early drafts. The paper benefited from internal review and detailed feedback over multiple rounds of revision; the resulting log of corrections is preserved in the replication archive. All errors are our own.

Author Contributions (CRediT)

writing—review and editing. **Paulo Furquim de Azevedo:** conceptualization, methodology, supervision, writing—review and editing.

Data and Code Availability

The CADE adjudication records used as ground truth are public and accessible through the *Conselho Administrativo de Defesa Econômica* portal (https://www.gov.br/cade). The São Paulo Bolsa Eletrônica de Compras (BEC) data are administrative records maintained by the State of São Paulo Treasury and were obtained through institutional channels. The replication archive containing the R, Python, and LaTeX source files, the construction scripts for all derived datasets, and the git history that produced the analysis is available upon publication via the journal's data-availability portal. The archive includes: (i) the canonical pipeline (`00_master.R` plus the build, clean, and analysis scripts) that regenerates all tables and figures from the four primary parquet files (`firm_loss_stats.parquet`, `firm_tender_map.parquet`, `FREQ_PARTICIP_rebuilt.parquet`, `LOSERS_rebuilt.parquet`); (ii) the institutional-identification scripts producing Table B.5; (iii) the cross-sector replication script producing Table B.4; and (iv) the inverse-CNAE mapping diagnostic discussed in Section 10.3.

Funding

The authors received no specific funding for this study.

Declarations of Interest

None.

Reproducibility Note

The numerical claims in this paper come from a single pipeline run on the canonical 2009–2019 BEC parquet files plus the CADE crossmatch CSV. The pipeline applies a strict 14-character CNPJ zero-padding convention before every merge, required to recover the full 193 FL–CADE co-bidder set; the convention is documented in the replication

archive so future replications reproduce the count deterministically. The firm-level AUC of 0.924 (95% CI [0.921, 0.926]) is computed against 193 adjudicated cobidder positives among 16,843 always-losers; the interval uses DeLong's method, with stratified percentile and BCa bootstrap intervals ($B = 5{,}000$ and 2,000 respectively) agreeing to three decimal places. The full sequence of commits that produced the final tables and figures lives in the replication archive's git log.
